Abstract

This paper estimates the impact of China's exchange rate changes on exports of developing countries in third markets. We use recent theory to develop an identification strategy in which the degree of competition between China and its developing country competitors in specific products and destinations plays a key role. We exploit the variation across exporters, importers, products and time—afforded both by disaggregated trade data and bilateral exchange rates—to estimate this "competitor country effect." We find robust evidence of a statistically and quantitatively significant effect. Our estimates suggest that a 10 percent appreciation of China's real exchange rate boosts a developing country's exports of a 4-digit HS product category to third markets on average by about 1.5-2 percent. The magnitude of the effect varies systematically with product characteristics as implied by theory.

Keywords: exchange rates, exports, China, competitor country

We are particularly grateful to Rob Feenstra for very detailed suggestions and advice. Martin Kessler and Ujjal Basu Roy provided excellent research assistance. All remaining errors are our own.

I. Introduction

Studying the effects of exchange rates is a hardy perennial of international macroeconomics. But nearly all the empirical research is focused on the impact on the country whose exchange rate changes.[1] There is less evidence on the effect of exchange rate movements on the exports of competitor countries, which in its adverse manifestation is dubbed the "beggar-thy-neighbor" effect.

This paper examines the effect of movements in China's exchange rate on exports of other developing countries in third country markets, which we will refer to throughout this paper as the "competitor country effect." We do not take a position in this paper on whether the renminbi is undervalued or whether changes in China's real exchange rate are attributable to nominal exchange rate policy, but simply focus on the trade consequences of these changes. [2] The Chinese currency provides a suitable opportunity to study this effect because China is not only the world's largest exporter of goods, it is also a highly diversified exporter, competing with a broad range of countries across the product spectrum. Figure 1 depicts a measure of how

[1] This is generally true of the older, voluminous literature on the trade consequences of exchange rates (Goldstein and Khan (1985) provides a survey and other contributions include Hooper, Johnson and Marquez (2000); Thursby and Thursby (1987)). It is also true of the more recent micro-literature on trade and exchange rates (Dekle and Ryoo (2007); Das, Roberts and Tybout (2001); Forbes (2002); Berman, Martin and Mayer (2012)); and of the recent literature on the growth consequences of exchange rates (Dooley et. al. (2003); Rodrik (2008); and Johnson et. al. (2010)).

[2] Du and Wei (2011) argue that a set of structural factors in China, by affecting savings and effective labor supply, can in principle explain the entire real exchange rate behavior, without much role for a nominal exchange rate policy. Also, Chinn and Wei (forthcoming) argue that the nominal exchange rate regime, and hence nominal exchange rate policy, does not promote adjustment of the trade balance because it does not reliably induce a change in the real exchange rate in the "correct" direction. They do, however, acknowledge that movements in the real exchange rate may affect goods trade, which is the focus of the present paper.

intensively each of the world's ten largest exporters competes with all other countries.[3] The measure ranges from zero (when the country is not a source of competition to any other country in any market for any product) to one (when the country is the sole exporter in all markets for all products). The value for China far surpasses that for all the other major exporters, including the United States and Germany, whose aggregate exports are not much smaller than those of China. Not surprisingly, China's dominant size and encompassing scope have made its exchange rate policy one of the most controversial aspects of international macroeconomics during the 2000s.

We estimate the competitor country effect using a novel methodology that allows us to exploit variation across four dimensions: exporters, importers, products, and time. We use disaggregated trade data at the 6-digit level, spanning 124 developing country exporters and 57 large importers over the period 2000-2008.

We also exploit the rich variation in China's exchange rate. Since we focus on the effects of China's exchange rate movements on exports of competitors in specific third country markets, we are able to use the bilateral exchange rate measures between China and the third country. Figure 2 illustrates that there is significant variation in these exchange rates across countries and over time. Although China's exchange rate appreciated for much of the period against the dollar (16 percent over 2000-08), this is not universally true vis-à-vis other currencies. For example, it depreciated substantially against the euro (33 percent over 2000-08), and also depreciated against sterling over much of the sample period (20 percent over 2000-07).

[3] We describe the measure of competition in more detail in Section II of the paper.

Our empirical approach is motivated by an analytical framework that we develop based on Feenstra, Obstfeld, and Russ (2012). The framework suggests an identification strategy that relies on the following reasoning: the more a country competes with China in a third market, the more a given depreciation of the renminbi is likely to hurt its exports in that market. We develop indices of competition between China and competing exporting countries at the exporter-importer-product level to implement this strategy. The empirical specification, with a battery of very general fixed effects that control for all observable and unobservable importer-exporter-product, importer-exporter-time, exporter-product-time and importer-product-time varying characteristics, helps us overcome to a large extent the problem of omitted variables that plagues estimation of trade-exchange rate equations using aggregated data. Moreover, our estimates are less susceptible to reverse causality concerns as exports, measured at a disaggregated level, are unlikely to affect a macroeconomic variable like the exchange rate, more so when the latter is the exchange rate of another country, China.[4]

We find robust evidence for the existence of a statistically and economically significant competitor country effect. In particular, exports to third markets of countries with a greater degree of competition with China tend to rise/fall significantly more as the renminbi appreciates/depreciates. Our estimates suggest that a 10 percent depreciation of the renminbi reduces a developing country's exports at the product-level on average by about 1.5-2 percent. For countries such as Nepal, Bangladesh, Philippines, Vietnam and Cambodia, the effect can be twice as high largely because they compete closely with China.

[4] See Engel (2009), for a discussion of how hard it is econometrically to separate out the effect of exchange rates on trade.

The estimated competitor country effects are robust to a variety of statistical tests, to alternative measures of exchange rates, to alternative disaggregation of the trade data, and to disaggregation by exporting and importing regions. They are also robust to incorporating the effect of competition from countries (other than China) whose currencies move with the renminbi.

We also find that the magnitude of the competitor country effect is consistent with the predictions from the analytical framework. For example, as implied by theory, the competitor country effect is greater for homogenous products with greater substitution possibilities than differentiated products. Further, this effect is attenuated for products that rely more on foreign inputs (and hence have a lower degree of Chinese domestic value added).

A few recent studies examine the effects of China's export performance, rather than its exchange rate, on other Asian countries (Hanson and Robertson (2008), Eichengreen, Rhee and Tong (2004) and Ahearne et. al. (2003)), or more recently the effects of Chinese import competition on US labor markets (Autor et. al. (2012). A few other papers examine the impact of exchange rate changes but on variables other than trade. For example, Eichengreen and Tong (2011) have recently estimated the effect of renminbi revaluation on stock market valuations of foreign firms.[5] There is no study so far on the effect of exchange rate changes on exports of other countries, even though this has been a central international concern going back to Robinson (1947) and the experience of the competitive devaluations prior to and during the Great Depression. This paper contributes towards filling this gap.

[5] Eichengreen and Tong (2011) find that renminbi appreciation has a positive effect on stock prices of firms in sectors competing with China, which is consistent with the findings in this paper.

The rest of the paper is organized as follows. In Section II, we set out the analytical framework. Section III elaborates the estimation strategy and Section IV describes the data. The results are presented and validated in Section V and Section VI concludes.

II. Analytical Framework

In order to develop an analytical framework for our empirical exercise, we use the model in Feenstra, Obstfeld and Russ (2012). The setting is as follows. There are J countries, H different goods. Each country produces a range of distinct varieties of each good. There is a constant elasticity of substitution (η) consumption index for the representative consumer in country j. Goods are differentiated not only by their characteristics, also by their country of origin (Armington assumption), with a constant elasticity of substitution between domestically produced and foreign varieties of good g (ω_g), and a constant elasticity of substitution between different varieties of good g originating in different exporters (σ_g). The same elasticity applies to different varieties of good g produced domestically.

Feenstra, Obstfeld and Russ (2012) show that we can express country j's imports from country i (equivalent to exports of country i to country j) of a particular good g, defined at the HS 6-digit level, V_g^{ij}, as follows (equation 11 in their paper).

$$(1)\quad V_g^{ij} = \left[\kappa_g^{ij}\left(\frac{P_g^{ij}}{P_g^{Fj}}\right)^{1-\sigma_g}\right] * \left[\left(1-\beta_g^{j}\right) * \left(\frac{P_g^{Fj}}{P_g^{j}}\right)^{1-\omega_g}\right] * \left[\alpha_g^{j}\left(\frac{P_g^{j}}{P^{j}}\right)^{1-\eta}\right] P_j C_j$$

That is, the proportion import demand (V_g^{ij}) of total consumption in , $P_j C_j$, depends on three sets of components: [6]

- the preference weight consumers in j attach to imports of good g from country i, κ_g^{ij}; the price of g imports by j from i, P_g^{ij}, relative to the price index of all g imports, P_g^{Fj} ; and the elasticity of substitution between imported varieties of g, σ_g;

- the preference weight consumers in j attach to domestically produced units of good g, β_g^j; the price index of all g imports by j, P_g^{Fj}, relative to the domestic price of good g, P_g^j; and the elasticity of substitution between the home and foreign varieties of good g, ω_g;

- the preference weight consumers in j attach to consumption of the g good, α_g^j; the price index of the g good, P_g^j, relative to the price index of all goods in j, P^j; and the elasticity of substitution between different goods, η.

We first establish the effect of a change in China's exchange rate changes vis-a-vis country j, E^{cj}, on country j's imports of a particular good g from country i, V_g^{ij} -- what we define as the "competitor country effect". We can express this as a chain effect, consisting of the effects of: the change in the Chinese exchange rate on the price of the Chinese good, the change in the price

[6] Note that we use imports and exports interchangeably throughout this paper, based on the simple identity that imports of a country A from another country say B are exactly the exports of B to A. In the empirical section, we use data reported by importing countries, which is generally regarded as more reliable than export data.

of the Chinese good on the foreign price index, and the change in the foreign price index on demand for good g from country i:

$$(2) \qquad \frac{\partial \ln V_g^{ij}}{\partial \ln E^{cj}} = \frac{\partial \ln P_g^{cj}}{\partial E^{cj}} * \frac{\partial \ln P_g^{Fj}}{\partial \ln P_g^{cj}} * \frac{\partial \ln V_g^{ij}}{\partial \ln P_g^{Fj}}$$

Now consider each term in the chain starting from the third term. Taking logs of Equation (1) and differentiating with respect to P_g^{Fj} under the assumption that a change in P_g^{Fj} has a negligible effect on the aggregate price index for good g in country j (P_g^j), we get:[7]

$$(3) \qquad \frac{\partial \ln V_g^{ij}}{\partial \ln P_g^{Fj}} = \sigma_g - \omega_g$$

This implies that the elasticity of demand for imports of good g from country i with respect to the foreign price index is simply the difference between the elasticity of substitution between imported varieties of g, σ_g, and the elasticity of substitution between home and foreign varieties, ω_g.

From Feenstra, Obstfeld and Russ (2012), we have the price index for imported goods, P_g^{Fj}, (their equation 5):

[7] The assumption that a change in say the U.S. import price index does not affect the U.S. domestic price index for a particular good is an innocuous assumption because any additional terms—for example aggregate destination-specific prices — will be absorbed in the very general fixed effects in the empirical estimation (see below). We do, however, allow for a change in the price of imports of a good from China to affect the U.S. import price index of the good (see equation (5) below).

(4) $$P_g^{Fj} = \left[\sum_{\substack{i=1 \\ i \neq j}}^{J} \kappa_g^{ij} \, (P_g^{ij})^{1-\sigma_g}\right]^{\frac{1}{1-\sigma_g}}$$

Taking logs, differentiating with respect to the price of the Chinese good g in the j market, P_g^{cj}, and simplifying, we get:

(5) $$\frac{\partial \ln P_g^{Fj}}{\partial \ln P_g^{cj}} = \frac{\kappa^{cj}(P^{cj})^{1-\sigma_g}}{\sum_{\substack{i=1 \\ i \neq j}}^{J} \kappa_g^{ij}(P_g^{ij})^{1-\sigma_g}} = s_g^{cj}$$

This implies that the elasticity of the foreign price index for good g with respect to the price of the Chinese good g is equal to the expenditure on the Chinese good as a share of expenditure on all imports of g, s_g^{cj}.

We assume that the price of the Chinese good in the j market, P_g^{cj}, depends on the price in China, P_g^c, the exchange rate, E^{cj} (defined in renminbi/importer currency), and an exponent which captures the extent of product-specific exchange rate pass-through from prices in China to j, μ_g^{cj}.

(6) $$P_g^{cj} = P_g^c (1/E^{cj})^{\mu_g^{cj}}$$

Differentiating with respect to the exchange rate, E^{cj}, we have:

$$\frac{\partial \ln P_g^{cj}}{\partial \ln E^{cj}} = -\mu_g^{cj} \tag{7}$$

Substituting from Equations (3), (5) and (7) in Equation (2), we get:

$$\frac{\partial \ln V_g^{ij}}{\partial \ln E^{cj}} = -(\sigma_g - \omega_g) s_g^{cj} \mu_g^{cj} \tag{8}$$

Equation (8) implies that a change in the Chinese exchange rate will have a negative effect on the import demand for good g only if (i) the elasticity of substitution across imported varieties is greater than that between imported and domestic varieties,[8] (ii) Chinese share in total imports of that good is strictly positive, and (iii) the exchange rate pass-through is non-zero.[9]

Given our assumption regarding the symmetric elasticity of substitution between imported varieties, σ_g, the effect of a change in China's exchange rate changes vis-à-vis country j, E^{cj}, on country j's imports of a good g from country i, V_g^{ij}, does not depend on any exporter attribute. This makes Equation (8) less amenable to empirical analysis. For example, if in order to test the prediction in Equation (8), we were to regress the import demand at the exporter-importer-product level on the Chinese exchange rate vis-à-vis the importing country, we would

[8] Feenstra, Obstfeld and Russ (2012) report median estimates of around 3 and 1 for σ_g and ω_g respectively.

[9] Note that in Broda and Weinstein (2006), $\sigma_g = \omega_g$, i.e. the elasticities of substitution between imported varieties equals the elasticity of substitution between home and foreign varieties. In our framework, if $\sigma_g = \omega_g$, in response to a renminbi depreciation, consumers in country j reduce their demand for varieties of good g produced at home and hence there is no competitor country effect.

not be able to include destination country fixed effects. We could, of course, strive to include all the relevant destination country attributes explicitly, but the effect of the exchange rate would not be estimated precisely because we would inevitably fail to control for certain unobserved sources of variation at the destination country (or destination-year) level.

One way to have such more general controls is to introduce more variation—for example, across exporters—in the right hand side of Equation (8). This would allow importer demand at the exporter-importer-product level to be regressed on a term that had all three sources of variation, which in turn would allow the inclusion of general fixed effects in the regression. To find such variation across exporters, we consider country j's imports, V_p^{ij}, from country i of a particular bundle of goods p, defined at a higher level of aggregation. In our empirical analysis, we use trade data at the Harmonized System (HS) 6-digit. Therefore g is defined at the HS 6-digit level. Country j's imports of p (at say the HS 4-digit level) can be expressed as:

$$V_p^{ij} = \sum_{g=1}^{G} V_g^{ij} \tag{9}$$

G denotes the number of HS 6-digit lines in the product category p. Taking logs and differentiating with respect to the exchange rate, E^{cj} and simplifying we get[10]

$$\frac{\partial \ln V_p^{ij}}{\partial \ln E^{cj}} = -\sum_{g=1}^{G} \left(\frac{V_g^{ij}}{\sum_g V_g^{ij}}\right) s_g^{cj} \mu_g^{cj} (\sigma_g - \omega_g) \tag{10}$$

[10] See the Appendix for the intermediate steps in deriving Equation (10).

This equation is intuitive because it captures the interplay between two ingredients that together determine the competitor country effect of China's exchange rate: the first is the relative importance of China as a source of imports of a good g in the importing country, s_g^{cj}; the second is the relative importance of that good g in the exports of the competitor country($\frac{V_g^{ij}}{\sum_g V_g^{ij}}$). More formally, the elasticity of say Brazil's exports to j at the HS 4-digit category with respect to China's exchange rate vis-à-vis j is related to the weighted average of China's share in total imports in each constituent 6 digit category which Brazil exports, where the weights are Brazil's exports in the corresponding 6 digit category as a share of its total exports in the 4 digit category.

Further, we also assume that the elasticities of substitution and the pass-through are identical for all HS 6-digit lines within each HS 4-digit category, but can vary across 4-digit categories, i.e. $\mu_g^{Cj} = \mu_p^{Cj}$, $\sigma_g - \omega_g = \sigma_p - \omega_p$. These assumptions help us to rewrite equation (10) to obtain a relatively simple expression for the competitor country effect, $\frac{\partial \ln V_p^{ij}}{\partial \ln E^{cj}}$,

$$\frac{\partial \ln V_p^{ij}}{\partial \ln E^{cj}} = I_{ijp}^V * [-\mu_p^{Cj} * (\sigma_p - \omega_p)] \tag{11}$$

where $I_{ijp}^V = \sum_{g=1}^{G} [(\frac{V_g^{ij}}{V_p^{ij}}) * s_g^{Cj}]$ is what we call the "value-based index of competition" (VBI) with China for good g exported from i to j. For example, if the HS 4-digit category, shirts, consisted of only two items, cotton shirts and non-cotton shirts, then our measure is simply the share of China in country j's imports of each type of shirt, weighted by the importance of each

type of shirt in country i's shirt exports to j. Equation (11) suggests that the elasticity of exports of a typical product to the importing country depends on: the index of competition; the two elasticities of substitution, σ and ω; and the extent of pass-through, μ.

With some additional symmetry assumptions, we can compute an alternative index of competition where we rely on the overlap between China's exports and those of country i, at the extensive margin. We first assume that for each 6 digit category that i exports to j within a 4-digit category, it exports the same amount. If i exports N_p^{ij} 6-digit categories in the relevant 4 digit category to j, then the first term in Equation (10) simplifies to $1/N_p^{ij}$. Next assume that in each 6 digit category within the relevant 4-digit category where i exports to j, China exports either a fixed share, s_p^{Cj}, or nothing. $s_g^{Cj} = s_p^{Cj}$ for $N_{p,Ch}^{ij}$ lines or zero otherwise. Then summing the second ratio over the relevant 6 digit lines gives us $s_p^{Cj} * N_{p,Ch}^{ij}$.

So that in this special case, Equation (11) can be written as:

$$\frac{\partial \ln V_p^{ij}}{\partial \ln E^{cj}} = I_{ijp}^{C} * [-s_p^{Cj} * \mu_p^{Cj} * (\sigma_p - \omega_p)] \tag{12}$$

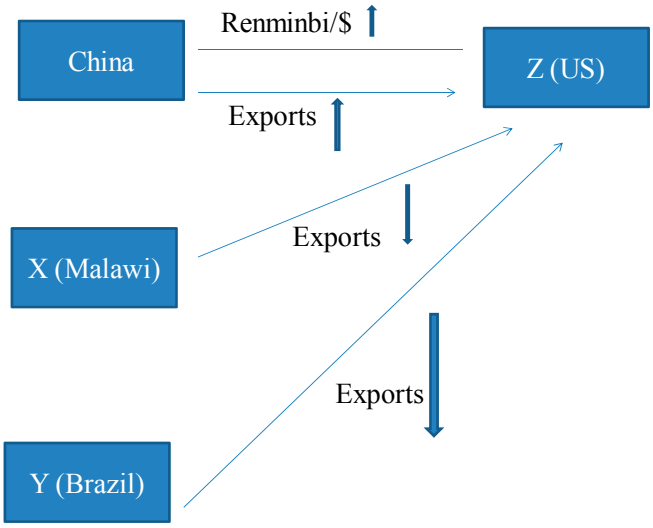
where $I_{ijp}^{C} = \frac{N_{p,Ch}^{ij}}{N_p^{ij}}$ is what we call the "count-based index" (CBI) of competition. The notion of competition in the CBI is based on whether or not China and its competitor commonly export a particular good (the extensive margin), and unlike the VBI, ignores the magnitudes of exports. Although this count-based index relies on symmetry assumptions, it provides a simple intuitive

measure of competition, and helps address some of the endogeneity concerns that could arise with the value-based index (see below).

III. Estimation Strategy

Equations (11) and (12) motivate the estimation of the competitor country effect. They imply two key predictions which we can take to the data: (i) the effect is less than zero (under plausible assumptions on elasticities) and (ii) the magnitude of this effect depends on the index of competition between China and its competing exporters. Higher is the degree of competition, larger is the magnitude of the competitor country effect.

Figure 3. Identification Strategy



Our identification strategy relies on the following intuition. Take two countries, Malawi and Brazil. Assume that Brazil faces a greater degree of competition with China in the US market for

a particular product. When the renminbi depreciates vis-à-vis the US$, exports from Brazil to the US for that product will fall more than exports from Malawi to the US (Figure 3).

This identification strategy yields the following estimating equation:

$$\ln V_{ijpt} = \beta I_{ijp} * \ln E_{jt} + v_{jpt} + s_{ipt} + \gamma_{ijt} + \theta_{ijp} + \epsilon_{ijpt} \quad (13)$$

where V_{ijpt} is the value of exports of HS 4-digit product p from country i to country j. E_{jt} is the Chinese exchange rate vis-à-vis j measured in renminbi per unit of j's currency. I_{ijp} is an index of competition between Chinese exports and those of its competitors as described in the analytical section. Note that the index does not have a time sub-script which we explain below. The interaction term combines the exchange rate between China and the importing country (say the renminbi-dollar exchange rate) and the index of competition between the exporter and China in the importing country.

Econometrically, an advantage of the formulation in equation (13) is that we can control for a wide range of omitted variables through a set of very general fixed effects. In fact, in our core estimations, we employ all three-way combinations of importer, exporter, product and time fixed effects. The term v_{jpt} captures any importer, product and time varying characteristics: one example would be fiscal support for the car industry in the United States. Similarly, the term s_{ipt} captures any exporter, product, and time-varying characteristics; for example, a productivity shock in Bangladesh that helped textile exports. Note that these fixed effects also encompass all

country-time shocks both on the importer and exporter side such as the business cycle in each country. The term γ_{ijt} captures any bilateral time-varying determinants of exports: for example, currency unions, and exchange rate pegs against particular currencies. The term θ_{ijp} captures bilateral product-specific characteristics: for example, all pre-existing preferential trade agreements that have product-specific tariffs and other barriers. The only factors that are not controlled for are policies of the importing country that vary by source country and product and time (for example, changes over time in product-specific preferential tariffs).[11] Finally, it is worth noting that our estimation strategy also controls for any possible effect on competitor countries stemming from productivity or other developments in China, whether exogenous or induced by exchange rates: if these are time-varying and product-specific, they will be absorbed in the s_{ipt} and v_{jpt} fixed effects.

Furthermore, our estimating equation is less susceptible to reverse causality from exports to exchange rates for two reasons: our dependent variable, disaggregated exports, is less likely to affect a macroeconomic variable like the exchange rate; moreover, the latter is the exchange rate of another country. What about reverse causality from the exports to the index of competition? Our count-based index, while derived from theory under symmetry assumptions, has the empirical virtue of being based on the extensive margin and not being measured in value terms; hence being less related to the left hand side variable and less afflicted by reverse causality problem. Our value based index is potentially more vulnerable to the reverse causality problem

[11] The lack of a comprehensive database on trade policies at the importer-exporter-product-time level makes it difficult to control for such effects.

because it is expressed in values, like the dependent variable. To minimize such endogeneity concerns we compute both indices for the initial period of the sample (i.e. for the year 2000).

IV. Data

We focus on the period 2000-2008, during which concerns about China's exchange rate policy have been most debated. For this period, we compile disaggregated data on bilateral exports from the UN Comtrade database. We collect data reported by the importing countries, which is generally regarded as more reliable than data on exports (i.e. exports from *i* to j are measured by imports of *j* from *i*). The data are for roughly 6000 non-oil HS 6-digit lines covering 900 4-digit products. We cover the 57 major importing countries (making sure that we include all countries that together accounted for over 95 percent of total exports of developing countries) and 124 developing country exporters which are potentially in competition with China (summary statistics are provided in Appendix Table 1 and the list of importing and exporting countries covered in Appendix Table 2).[12] The list of developing countries is based on World Bank country classification, and is comprised of all low and middle income countries (2010 GNI per capita of $12,275 or less).

[12] In principle, we could include all exporting countries in our sample. We choose to restrict the analysis to developing country exporters, largely due to computational constraints. However, this restricted choice also stems from the fact that developing countries compete more with China than industrial countries do: the average index of competition between the former set and China is about 0.4 and 0.9, respectively for the value based and count based indices of competition. The corresponding numbers for industrial countries are 0.1 and 0.7, respectively.

The trade data are reported in current US dollars, and are deflated by the US CPI. We recognize that ideally we would use bilateral price indices to deflate trade between different country pairs but such bilateral deflators are not available. However, the presence of the very general fixed effects has the consequence also of implicitly deflating the trade data. The data are implicitly deflated by prices that vary by importer, product and time; by importer, product and exporter; and by exporter, product and time. They are, however, not deflated by prices that vary along all four dimensions (importer, exporter, product, and time).

Exchange rate data are from the IMF's International Financial Statistics (IFS) database. In the theoretical framework, the key price that determines the transmission mechanism of exchange rate changes is the price in the importing market charged by China's exporters. Equation (6) suggests that this price is determined by the domestic price of the good in China, the China-importer bilateral exchange rate and the pass-through. The pass-through parameter will be absorbed in our estimated coefficients and our core exchange rate measure will, therefore, be the bilateral exchange rate for China vis-à-vis the importing country (measured as renminbi per importing country currency), deflated by China's CPI. We use the term "real exchange rate" throughout the paper to denote this measure. For robustness, in the empirical analysis, we also use various alternative exchange rate measures like the nominal bilateral exchange rate between China and the importing country, the same adjusted by domestic and foreign CPI; the nominal and real effective exchange rate (all from the IMF), and also the internal real exchange rate (a measure of the relative price of tradables to nontradables) from the Penn World Tables.

Before we present the econometric results, it is worth looking at some basic data. Figure 4 plots China's average index of competition (where the average is over all exporters and products). The index is measured in two ways consistent with the discussion in the analytical section. Both the VBI and the CBI rise over time, consistent with China becoming a bigger and more diverse exporter. The CBI shows in particular that by 2008, on average, China occupies nearly all the product space of other developing country exporters. Figures 5a and 5b plot the same indices but disaggregated by region. These charts show that China's overlap with all regions has risen steadily over time, with the level of the overlap greatest with other exporters in Asia (over 95 percent in 2008 for the CBI) and least with Europe and Central Asia.

V. Results

Main findings and robustness

All results are presented for both variations of our competition index. In Table 1, we present the baseline results. Our core sample has nearly 3.6 million observations. Columns [1]-[4] use the value-based index (VBI) while columns [5]-[8] use the count-based index (CBI). In both cases, the number of fixed effects progressively increase across the specifications, with a comprehensive set of fixed effects in columns [4] and [8], making the specification a very demanding one. These will constitute our core specifications. All regressions are clustered at the importer-exporter-product level.

We find that the coefficient on the interaction term between the Chinese exchange rate and the index of competition is consistently negative and significant at the 1 percent confidence level. In

other words, a depreciation of the Chinese exchange rate vis-à-vis say the dollar is associated with a greater reduction in a developing country's exports of a particular product to the United States, the more that country is in competition with China in that product in the United States.

We subject this core specification to a series of robustness checks in Tables 2-6. In Table 2, column [1], we drop outliers, defined as the top and bottom 1 percentile of observations. The key coefficient is negative and statistically significant with the magnitudes close to those for the larger, core sample. In columns [2]-[4], we cluster the standard errors at the exporter-importer-year, exporter-product-year and importer-product year levels, and the statistical significance of the coefficients remain unchanged.[13]

In columns [5] and [6], to make sure that the results are not driven by the choice of year for measuring the index of competition, we measure the index for the years 2001 and 2002, respectively. In column [7], we use an alternative measure of competition—the export similarity index due to Finger and Kreinin (1979).[14] Thus, for a wide range of robustness tests, the core

[13] Clustering the standard errors at a higher level of aggregation (importer-exporter, importer-product, or exporter-product) also does not alter the significance of our findings.

[14] The Finger-Kreinin index can be expressed as: $FK_{ijpt} = \sum_g \min\left[\frac{X_{ijgt}}{\sum_g X_{ijgt}}, \frac{X_{Cjgt}}{\sum_g X_{Cjgt}}\right]$ where

$\frac{X_{ijgt}}{\sum_g X_{ijgt}} = \text{Share of product } g \text{ in total exports from } i \text{ to } j \text{ at the 4-digit level}$

$\frac{X_{Cjgt}}{\sum_g X_{Cjgt}} = \text{Share of product } g \text{ in total exports from China to } j \text{ at the 4-digit level.}$

The results are also robust to using the alternative formulation of the Finger-Kreinin Index defined as

results remain unaltered, both in the sense that the coefficients are stable and consistently significant at the 1 percent confidence level.

In Table 3, we test for robustness to alternative measures of the exchange rate variable. In our analytical framework, we assumed that the price of Chinese goods in the importing country market is determined by a simple relationship between domestic prices in China and exchange rate pass-through. Based on the framework, in our core specifications, we deflate the nominal bilateral exchange rate (between China and the importing country) by Chinese prices. The implicit assumption here is that Chinese producers take account of changes in the bilateral exchange rate and average domestic inflation to determine export prices. However, Chinese producers and exporters could determine their destination-specific export prices in different ways. One possibility is that Chinese producers could be influenced by the nominal bilateral exchange rate (E_{jt}) or by the real bilateral exchange rate ($E_{jt} * P_{jt}/P_t^C$), with P_{jt} and P_t^C denoting prices in the importing country and China respectively. The specifications corresponding to these two ways of measuring the exchange rate are in columns [1] and [2] (for the VBI) and columns [6] and [7] (for the CBI). In both cases, the results are robust, although the magnitudes decline relative to the core specification.

$$FK_{ijpt} = 1 - \frac{1}{2}\sum_g \left| \frac{X_{ijgt}}{\sum_g X_{ijgt}} - \frac{X_{Cjgt}}{\sum_g X_{Cjgt}} \right|$$

and the weighted Finger-Krenin Index defined as

$$WFK_{ijpt} = \sum_g \quad \frac{X_{ijgt}}{\sum_k X_{ijgt}} * [1 - \frac{X_{ijgt} - X_{Cjgt}}{X_{ijgt} + X_{Cjgt}}]$$

.

Yet other models of pricing behavior could involve Chinese producers looking at changes in their multilateral competitiveness in determining destination-specific export prices. In this case, the relevant exchange rate is not destination specific but a multilateral one that is identical across all importers (ME_t) where ME stands for China's multilateral exchange rate and hence without a j subscript).[15] We re-estimate the core regression to cater to these possibilities by using the IMF's effective exchange rate as the relevant measure with the nominal rate in columns [3] and [8], and the real rate in columns [4] and [9]. Again, the coefficients are correctly signed and significant at the 1 percent confidence level. Interestingly, these coefficients are substantially greater than for the core specification.

In all these specifications, exchange rates are measured as the relative price of two different currencies. An alternative way of measuring real exchange rates—sometimes called the internal real exchange rate—is as the relative price of tradables to nontradables within a country. This exchange rate is available from the Penn World Tables from the series that measures the price level of GDP.[16] In columns [5] and [10], we use this measure of China's real exchange rate. Again, we find that the coefficient on the interaction term is significant at the 1 percent level, and is greater in magnitude than in the core specification.[17]

[15] Note that in this case, the exchange rate varies across time and the index varies across importer, exporter, and product so that the interaction term exploits the variation across all four dimensions.
[16] A higher price level is associated with a higher price of non-tradables and hence signifies an appreciation of the real exchange rate (see Rogoff, 1996). This exchange rate variable, like the IMF's nominal and effective exchange rate series, is a multilateral variable, and hence varies only by time and not across importers.
[17] Note that an increase in all the effective exchange rate measures in columns [3]-[5], and [8]-[10] denotes an appreciation (unlike in columns [1]-[2], and [6]-[7], and our baseline exchange rate measures in Tables 1 and 2). Hence, a positive coefficient on the interaction terms in these columns is consistent with our main findings.

One potential omitted variable issue arises in regard to our core specification. Our finding that the typical developing country's exports are adversely affected when China's currency depreciates has not yet addressed an important question: what if other countries respond to China's depreciation by devaluing their own currencies? In Table 4, we control for this possibility. Among the developing countries which are the top exporters, we identify those whose currencies are most closely correlated with that of China (in real effective terms) during the period 2000-08.[18] We interact the exchange rates of each of these countries with the respective index of competition of each with the exporting country, where the index is defined analogous to that of China in equations (11) and (12).

In columns [1] and [4], we include countries whose exchange rates have a correlation coefficient relative to the renminbi that is greater than 0.7. So we add two additional regressors (one for each country) to the core specification. In each case, the regressor is the interaction between the country's exchange rate and that country's index of competition with other countries. In columns [2] and [5], we repeat this procedure to include countries whose correlation coefficients with the renminbi are more than 0.4. In columns [3] and [6], the threshold correlation coefficient is 0.3. For presentational reasons, we only show the impact on the main coefficient of interest, namely that relating to China. This coefficient remains significant at the 1 percent confidence level, although it is slightly reduced in magnitude. Overall, these results suggest that our main finding related to the competitor country effect of the Chinese exchange rate remains strong and

[18] We include the top 10 exporters (after China) based on total exports between 2000 and 2008. Developing countries' index of competition with other non-significant exporters is likely to be much smaller, and hence exchange rate movements in these countries is less likely to displace exports of other developing countries.

robust to inclusion of possible omitted variables. Thus, exporters competing with China suffer because of a renminbi depreciation and not (or not just) because they are adversely affected by the depreciation of currencies that closely track the renminbi.

We do find statistically significant and negative coefficients on the interaction terms for the other countries.[19] Hence, the competitor country effect we estimate is not specific to China, and is more general. Unsurprisingly, the indices of competition are much lower for all the other countries. Therefore, the magnitude of the competitor country effect which is given by the coefficient multiplied by the index is much smaller for the other countries than for China.[20]

In Table 5, we test for robustness across exporters, defined in geographic terms. We split the sample into four regions and find that the results hold across all. The coefficients on the China competitor country effect are greater for Asia than for sub-Saharan Africa but it is difficult to say whether these differences are due to the fact of supply conditions in the exporting region or due to differences in the product composition of their exports and/or their geographic destination.[21]

In Table 6, we check if the results are robust to the degree of product disaggregation. In the core specification, the data are at the HS 4-digit level. In Table 6, we use data at the HS 2-digit level.

[19] These results are available upon request.
[20] See Section V for detailed discussion on the magnitudes of the coefficients.
[21] The differences are also statistically significant (based on a estimating a stacked specification with triple interaction terms with regional dummies). We find some suggestive evidence that the differences between Asia and sub-Saharan Africa, for example, may be due to the fact that the latters' exports tend to be less homogenous than those of Asia. We also tested for robustness across importers, defined in terms of advanced and other countries, and the results hold for each category of importers.

The indices of competition are measured by aggregating across 6-digit lines within the 2-digit category. The sample size shrinks from over 3.6 million to about 860,000 observations. But the interaction term remains negative and significant.

In Table 7, we test whether our results are robust to alternative time frames for exchange rate effects to be felt. Our core specification uses annual data. To test whether the results hold for the medium run, we use a long difference approach suggested by Acemoglu and Johnson (2007). Thus, in column [1], we use observations only for 2000 and 2008 and find that the results remain similar to the baseline, with the magnitude of the interaction coefficient increasing by a little relative to the core specification. In columns [2] and [3], we use one and two-year lags for the exchange rate, respectively, and find that the exchange rate effect persists, although the magnitude declines over time.

To assess long-run effects, ideally, we would estimate Generalize Method of Moments (GMM) regressions with a lagged dependent variable but this is computationally infeasible on such a large sample with multiple sources of variation. Instead, we estimate our baseline regression including the lagged dependent variable (column [4], Table 7), recognizing that there is a downward bias that afflicts in particular the lagged dependent variable.[22] The key exchange rate variable is significant for both indices of competition. Interestingly, the implied long-run effect of the exchange rate in this specification (0.57 and 0.37 for the value and count-based indices of competition, respectively) is greater than the effect in the core specification. Given the

[22] The bias, however, tends to decrease with a large number of cross-section units (Buddelmeyer et. al., 2008).

limitations of this regression, this result must be treated with caution but it is not inconsistent with the notion that exchange rate changes have large long-term effects.[23]

Overall, the results in Tables 1-7 confirm the predictions from the analytical framework. The elasticity of developing country exports with respect to Chinese exchange rate is consistently and robustly negative. Further, this elasticity depends on the index of competition: a given depreciation of the renminbi is associated with a bigger reduction in developing country exports the higher this index.

Competitor country effect and product characteristics

Equations [11] and [12] suggest that the competitor country effect should vary according to two product attributes: elasticity of substitution (σ_p) between different imported varieties and exchange rate pass through (μ_p). Higher the values of σ_p and μ_p , the larger should be this effect.

First, we analyze how the competitor country effect varies by the degree of substitution between products. We partition the data into homogenous (i.e. those with a greater degree of

[23] We also test for asymmetric exchange rate effects. The richness of our sample, in particular the variation across importing countries and time, allows us to distinguish episodes of depreciations and appreciations and test whether there are differential effects. The results (available from the authors) show that both depreciations and appreciations have statistically significant and economically large effects.

substitutability) and differentiated products based on Rauch's (1999) classification.[24] As shown in Table 8, columns [1], [2], [4] and [5], we find that the coefficients on the interaction between the index of competition and exchange rates are higher in magnitude for homogenous products vis-à-vis differentiated ones. Columns [3] and [6] confirm that the differences between the coefficients for the two types of goods are statistically significant. The differences are substantial: for the count-based and value-based indices, the coefficients on homogenous goods are about 20 and 40 percent greater, respectively than for differentiated goods.

Second, we explore how the competitor country effect is related to a likely determinant of Chinese exchange rate pass-through – the imported intermediate content of Chinese exports. One of the key features of Chinese manufacturing exports has been the extent to which they have relied on foreign intermediate inputs (Kee and Tang, 2012, Koopman, Wang and Wei (forthcoming)). The greater the reliance on foreign inputs (lower the domestic value added), the more an exchange rate depreciation will increase input costs and hence dampen the competitive advantage from a depreciation. In other words, a greater reliance on foreign inputs is analytically analogous to a lower pass-through which theory predicts will dampen the competitor country effect. We test this proposition in the data. We use the classification in Koopman, Wang and Wei (forthcoming) to divide our data into two samples: those characterized by a high degree of foreign inputs and those with a low degree.[25]

[24] Note that Rauch's classification is available at the SITC 4-digit; we concord it to HS 6-digit level using standard concordance tables, and then partition the data into homogenous and differentiated using Rauch's liberal classification (reference priced goods are included in the homogenous category). We then aggregate the data to the HS 4-digit level.

[25] The classification of sectors by domestic value added is restricted to manufacturing, and is based on ISIC data which we concorded with HS 4-digit data.

In Table 9 we estimate our core specification for each of these samples. We find that, consistent with theory, our competitor country effect is in fact dampened for products with a high degree of foreign inputs (compare columns [2] versus [1] and [5] versus [4]). Columns [3] and [6] confirm that the differences between the two samples are statistically different: the coefficient on the core interaction term is about 13 percent greater (in absolute value) for the sample with the lower degree of foreign intermediate inputs in the case of the value based index and 10 percent greater for the count-based index.[26]

Discussion of Magnitudes

Recall that the competitor country effect we estimate in equation (13) is given by:

$$\frac{\partial \ln V_{ijpt}}{\partial \ln E_{jt}} = I_{ijp} * \beta$$

Our estimations identify β which we can multiply by the relevant value of the index of competition to obtain the average competitor country effect. The range of estimates for different combinations of the two indices of competition and estimates of β are shown in Table 10. For the baseline estimate of our elasticity (columns [4] and [8] in Table 1) and for the median index of competition, we get a total effect of -0.14 and -0.20 for the value and count-based indices

[26] The same result holds for an alternative classification by share of processing exports (with high domestic value added products being those with low share of processing) due to Koopman et. al. (forthcoming). The extent of pass-through is also likely to depend on whether trade is governed by contracts (see e.g. Hellerstein, 2008) and the currency in which goods are priced; for example, goods priced in dollars are likely to see less pass-through than goods priced in the national currency of the exporter (see Gopinath, Itskhoki and Rigobon, 2011). The absence of a sufficiently disaggregated cross-country database on measures of pass-through precludes us from including these additional dimensions in our analysis.

respectively. The estimates imply that a 10 percent depreciation/appreciation of the renminbi is associated with a reduction/increase in developing country exports at the product level to a third market of about 1.5-2 percent.

For countries that are in the 90th percentile in terms of competition with China, the range of baseline estimates increases to 2-3 percent for the two indices. If we use the higher values of β corresponding to e.g. multilateral measure of exchange rates (column 5 in Table 3), the magnitude of the estimates increases substantially. For the indices of competition in the 90th percentile, the competitor country effect could be as high as 6 percent for a 10 percent change in the renminbi.[27]

How do our empirical estimates compare with those suggested by the analytical framework? Equations (11) and (12) yield theoretical magnitudes for the competitor country effect. From the existing literature, we can obtain estimated values for each of the parameters. Of course, there is wide variation in each of these, but some ball-park estimates are the following: $\sigma=3$, $\omega=1$, $\mu=0.4$ and $s=0.4$. The estimates of σ (the elasticity of substitution between imported goods, or the micro-Armington elasticity) and ω (the elasticity of substitution between domestic and imported goods, or the macro-Armington elasticity) are based on Feenstra, Obstfeld and Russ

[27] Note that even using the estimates from Table 4, where we control for movements in other currencies, the competitor country effect of China's exchange rate movements is in the range of 1-2 percent. We also conduct another exercise where we assume that a movement in the renminbi is followed by movements in other correlated currencies. Based on our estimates from Table 4, the overall effect of movements in all these currencies is also in the range of 1-2 percent. This is due to the fact that competitor country effect of other currencies is much smaller in magnitude than China's. Although the coefficients on the interaction terms are similar, the indices of competition are much smaller for the other countries. These results are available upon request.

(2011). The pass-through coefficient (μ) is an average of the estimates from Campa and Goldberg (2005) for industrial countries and the estimates of Gopinath, Itskhoki and Rigobon (2011) for the United States.[28] The average share of China, s, in the markets of each of the importing countries is obtained from our data.

Combining these estimates with the average value of the index of competition for the value (I_{ijp}^{V}) and count-based (I_{ijp}^{C}) indices from our data (of 0.4 and 0.9, respectively), yield a magnitude of the third-market effect of -0.32 for the value-based index and -0.29 for the count-based index. Therefore, theory appears to predict a competitor country effect of about 0.3. For the count-based index, the theoretical and our baseline empirical estimates (-0.2) are not far apart. For the value-based index, our baseline empirical estimates are below those derived from theory (0.14 versus 0.32). There are two possible explanations. Residual measurement errors would impart a natural attenuation bias to the econometric estimates. Second, the values of the elasticity of substitution that we use to derive the theoretical prediction are based on Feenstra, Obstfeld and Russ (2012), who estimate the elasticity for goods at a level of disaggregation close to the HS 10-digit level. Our data on the other hand are at HS 4-digit so that the relevant elasticity for our purpose could be well below the value of 3 that we use here.[29] Such a lower value would bring our empirical estimates closer to those based on theory.

[28] Goldberg and Knetter (1997) and Goldberg and Hellerstein (2008) also provide evidence on pass-through and its decline over time. Xing (2010) looks specifically at pass-through of Chinese exchange rates to import prices in US and Japan, and estimates pass-through coefficients of 0.23 and 0.56 for the US and Japan respectively.

[29] Broda and Weinstein (2006) argue that with more disaggregated data, one is likely to find higher estimates of the elasticity of substitution.

Overall, the baseline estimates in this paper suggest that a 10 percent depreciation/appreciation in the renminbi exchange rate vis-à-vis an importing country decreases/increases on average developing country exports by about 1.5-2 percent. Given the 30 percent *appreciation* of China's real exchange rate vis-à-vis the US dollar over 2000-2008, our findings suggest that this could have been associated with about a 4.5-6 percent increase in the typical developing country's exports to the US, with much greater effects for countries in closer competition with China.[30]

VI. Conclusion

To our knowledge, this paper is the first attempt to quantify the effect of exchange rate changes on the exports of competitor countries to third markets—the competitor country effect—that both exploits the rich variation afforded by disaggregated trade data and does so in a manner that is motivated by and consistent with theory. We study the case of China and find that its exchange rate changes can have significant and robust competitor country effects.

These findings may have important policy implications for developing countries and for the multilateral system if real exchange rate movements (or the lack thereof) stem from policy action. Since we have found that the resulting competitor country effects are significant, one country's policies can have substantial export implications for other countries. In these circumstances, designing and implementing multilateral rules on exchange rate policies to manage and minimize the competitor country effects may be necessary (Mattoo and Subramanian, 2008).

[30] Note that the renminbi-dollar rate appreciated by only 16 percent in nominal terms (as shown in Figure 2); however the appreciation is almost double in real terms when we take into account Chinese inflation.

Importantly, we would emphasize that this paper identifies precisely and in a robust way a very specific mechanism of influence from exchange rates to trade (the "competitor country effect" of Chinese exchange rate movements on exports of competitor countries to third markets). There could be other effects on developing country exports to China which we do not measure. For example, a depreciation of the renminbi could increase developing country exports of raw materials and intermediate goods to China to be used in the production of China's exports to third countries. Similarly, if China's depreciation boosts its own growth, that could increase its demand for all goods and services, which could also lead to greater developing country exports. Thus, the effect of China's exchange rate on overall exports of other countries remains an open question. Also, this paper has focused on the effects of the exchange rate on the intensive margin of exports, i.e. how much is exported, and not on the extensive margin, i.e. on whether a country exports at all.[31] Finally, we have not directly estimated any effects of China's exchange rate movements on its own exports. Further research is needed to precisely identify all these other effects.

[31] As Helpman, Melitz and Rubinstein (2008) have argued, any resultant bias is mostly due to the omission of the extensive margins rather than selection. However, their two-stage estimation procedure, using a selection equation in the first stage, is hard to implement in the present context because it would require an instrument that varies with sectors, time and country-pairs and affects the decision to export and not the magnitude of exports. An alternative approach, due to Santos Silva and Tenreyro (2006), is rendered difficult because of the large battery of fixed effects we have included in our specifications.

Notes. The figure shows an average index of competition (what we will call later in the text, the "value-based index of competition" or VBI) with the world's top 10 exporters of goods measured by value of exports (excluding oil). The index is first constructed at the exporter-importer-HS 4-digit product level. It is defined as the weighted average of share of the relevant exporter (e.g. China) in the overall imports of a HS 6-digit product, with the weights being the share of that 6-digit product in the exports of the relevant HS 4-digit category. To arrive at a single country-level measure, we take simple averages over all HS 4-digit products, importers and exporters.

Notes. The figure shows averages over time for the value and count-based indices of competition. The indices are measured at the exporter-importer-HS 4-digit product-time level. The value-based index is defined as the summation over all 6-digit products within the 4-digit category of the following: share of China in overall imports of a 6 digit product multiplied by the share of the 6-digit product in total 4-digit exports from the exporter to the importer. The count-based index of competition with China is defined at the 4-digit product level, and is equal to the share of 6-digit products within a 4-digit category that i exports to j, that China also exports to j.

importer*product*time	N	Y	Y	Y	N	Y	Y	Y

Notes. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. The index of competition in columns [1]-[4] is defined as the summation over all 6-digit products within the 4-digit category of the following: share of China in overall imports of a 6 digit product multiplied by the share of the 6-digit product in total 4-digit exports from the exporter to the importer. The index of competition with China in columns [5]-[8], is defined at the 4-digit product level, and is equal to the share of 6-digit products within a 4-digit category that i exports to j, that China also exports to j. The index of competition in all the columns is measured in the year 2000. The regression sample includes years from 2000-2008. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 2. Robustness

Dependent variable = log(exports) at (exporter,importer, 4-digit product, year) level

Notes. See notes to Table 1 for definitions of the value-based and count-based index of competition. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. In column [1], the top and bottom fifth percentile of the observations are dropped. In columns [2]-[4], we make alternative assumptions on clustering the standard errors. In columns [5] and [6], the index of competition is measured in 2001 and 2002 respectively. In Column [7], we use the Finger-Krenin index of export similarity. The index of competition except in columns [5] and [6] is measured in the year 2000. The regression sample includes years from 2000-2008. All regressions include exporter*importer*time, exporter*product*time, importer*product time, and exporter*importer*product fixed effects. Standard errors denoted in parentheses are clustered at the importer*exporter*product level (except in columns [3]-[5]) . ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 3. Robustness to Alternative Exchange Rate Measures

Dependent variable = log(exports) at (exporter,importer, 4-digit product, year) level

	Value-based index of competition					Count-based index of competition				
	[1]	[2]	[3]	[4]	[5]	[6]	[7]	[8]	[9]	[10]

N	3,586,936	3,586,936	3,602,228	3,602,228	3,602,228	3,586,936	3,586,936	3,602,228	3,602,228	3,602,228

Notes. See notes to Table 1 for definitions of the value-based and count-based index of competition. In columns [1] and [5], nominal exchange rate of importer wrt China is measured as renminbi/importer currency. In columns [2] and [6], real exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI relative to importer CPI. In columns [3] and [7], nominal effective exchange rate of China (2005=100) from the IMF is used. In columns [4] and [8], real effective exchange rate of China (2005=100) from the IMF is used. Note that an increase in the real and nominal effective exchange rates denotes an appreciation. In columns [5] and [10], the measure of the real exchange rate is the price level of GDP (series p) from the Penn World Tables (version 7), which is the ratio of GDP at market exchange rates to GDP at purchasing power parity exchange rates. The price level is expressed relative to that of the United States. An increase in the price level denotes an appreciation of the real exchange rate. The regression sample in all regressions includes years from 2000-2008. All regressions include exporter*importer*time, exporter*product*time, importer*product time, and exporter*importer*product fixed effects. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 4. Robustness to Omitted Variables

Dependent variable = log(exports) at (exporter,importer,4-digit product, year) level

importer*product*time	Y	Y	Y	Y	Y	Y

Notes. The control countries are among the top ten exporters in the world, whose real effective exchange rates are highly correlated with the Chinese. Exchange rate of importer wrt e.g. China is measured as renminbi/importer currency, deflated by the Chinese CPI. The exchange rate of importer wrt other countries is also measured in a similar way.The index of competition in columns [1]-[3] is defined as the summation over all 6-digit products within the 4-digit category of the following: share of China/Malaysia/South Africa, etc. in overall imports of a 6 digit product multiplied by the share of the 6-digit product in total 4-digit exports from the exporter to the importer. The index of competition with China/Malaysia/South Africa, etc. in columns [4]-[6], is defined at the 4-digit product level, and is equal to the share of 6-digit products within a 4-digit category that i exports to j, that China/Malaysia/South Africa also exports to j. The index of competition in all the columns is measured in the year 2000. The regression sample includes years from 2000-2008. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 5. Robustness By Region of Exporter

Dependent variable = log(exports) at (exporter,importer,4-digit product, year) level

	Value-based index				Count-based index			
	Asia	Europe	LAC	MENA+SSA	Asia	Europe	LAC	MENA+SSA
Index of competition with China*log(exchange rate of importer with respect to China)	-0.467***	-0.433***	-0.297***	-0.116***	-0.288***	-0.258***	-0.192***	-0.139***

Notes. The region of the exporter is defined based on the World Bank country classification. See notes to Table 1 for definitions of the valuey-based and count-based index of competition. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. The index of competition in all the columns is measured in the year 2000. The regression sample includes years from 2000-2008. LAC denotes Latin America and the Caribbean; MENA denotes the Middle East and North Africa; SSA denotes Sub-Saharan Africa. All regressions include exporter*importer*time, exporter*product*time, importer*product time, and exporter*importer*product fixed effects. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 6. Robustness to Degree of Product Aggregation (HS 2-Digit Level)

Dependent variable = log(exports) at (exporter,importer,2-digit product, year) level

importer*product*time	N	Y	Y	Y	N	Y	Y	Y

Notes. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. The index of competition in columns [1]-[4] is defined as the summation over all 6-digit products within the 2-digit category of the following: share of China in overall imports of a 6 digit product multiplied by the share of the 6-digit product in total 2-digit exports from the exporter to the importer. The index of competition with China in columns [5]-[8], is defined at the 2-digit product level, and is equal to the share of 6-digit products within a 2-digit category that i exports to j, that China also exports to j. The index of competition in all the columns is measured in the year 2000. The regression sample includes years from 2000-2008. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Notes. See notes to Table 1 for definitions of the value-based and count-based index of competition. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. In column [1], we retsrict the sample to two years -- 2000 and 2008. . Exchange rate is lagged by one year in column [2], and by two years in columns [3]. log(exports) lagged by one year is included as an additional explanatory variable in column [4]. The index of competition is measured in the year 2000 in all the columns. In columns [5] and [6], depreciations and appreciations are defined by those observations wheerby the exchange rate increased and decreased respectively. All regressions include exporter*importer*time, exporter*product*time, importer*product time, and exporter*importer*product fixed effects. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 8. Products Distinguished by Degree of Differentiation

Notes. Goods are classified into homogeneous or differentiated according to Rauch's liberal classification at 6-digit level. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. The index of competition in all the columns is measured in the year 2000. The regression sample includes years from 2000-2008. All regressions include exporter*importer*time, exporter*product*time, importer*product time, and exporter*importer*product fixed effects. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 9. Products Distinguished by Domestic Value Added

Dependent variable = log(exports) at (exporter,importer, 4-digit product, year) level

	Value-based index			Count-based index		
	High domestic value added	Low domestic value added	Interaction	High domestic value added	Low domestic value added	Interaction

N	1,511,450	1,830,310	3,341,760	1,738,687	1,848,249	3,341,760

Notes. Regressions are restricted to manufacturing only. The data on share of domestic value added for products in the manufacturing sector is from Koopman, Wang and Wei (forthcoming). Goods are classified into high and low-value added based on values above and below the median. See notes to Table 1 for definitions of the value-based and count-based index of competition. Exchange rate of importer wrt China is measured as renminbi/importer currency, deflated by the Chinese CPI. The index of competition in all the columns is measured in the year 2000. The regression sample includes years from 2000-2008. All regressions include exporter*importer*time, exporter*product*time, importer*product time, and exporter*importer*product fixed effects. Standard errors denoted in parentheses are clustered at the importer*exporter*product level. ***, ** and * denote statistical significance at the 1, 5 and 10 percent respectively.

Table 10. Range of Estimated Spillover Effect of a 10 percent Depreciation of Chinese Exchange Rate

	Value-based index			Count-based index		
Beta coefficients →	Baseline	Minimum	Maximum	Baseline	Minimum	Maximum
Percentile of the index of competition ↓						
10	-0.01	0.00	-0.01	0.00	0.00	0.00
50	-1.30	-0.47	-2.52	-1.99	-1.39	-3.74
90	-3.12	-1.13	-6.03	-2.22	-1.55	-4.17

Notes. For the value-based index, the baseline, minimum and maximum values of the estimated coefficients correspond to column [4], Table 1; column [3], Table 1; and column [5], Table 3 respectively. For the count-based index, the baseline, minimum and maximum values of the estimated coefficients correspond to column [8], Table 1; column [4], Table 4; and column [7], Table 2 respectively.

Appendix for Online Publication

Steps in the Derivation of Equation (10)

From Equation (9),

$$\frac{\partial lnV_p^{ij}}{\partial lnE^{Cj}} = \frac{\partial \ln\ (\sum_{g=1}^{G} V_g^{ij})}{\partial \ln E^{Cj}}$$

Applying the formula: $dlny = dy/y$

$$\frac{\partial lnV_p^{ij}}{\partial lnE^{Cj}} = \frac{1}{\sum_{g=1}^{G} V_g^{ij}} \frac{\partial\ (\sum_{g=1}^{G} V_g^{ij})}{\partial lnE^{Cj}}$$

Applying the identity: $\left(\frac{d\sum y}{dx} = \sum \frac{dy}{dx}\right)$

$$\frac{\partial\ lnV_p^{ij}}{\partial lnE^{Cj}} = \frac{1}{\sum_{g=1}^{G} V_g^{ij}} \sum_{g=1}^{G} \frac{\partial V_g^{ij}}{\partial lnE^{Cj}}$$

Further, applying the formula: $\frac{\partial y}{\partial \ln x} = y \frac{\partial lny}{\partial \ln x}$

$$\frac{\partial\ lnV_p^{ij}}{\partial\ lnE^{Cj}} = \frac{1}{\sum_{g=1}^{G} V_g^{ij}} \sum_{g=1}^{G} V_g^{ij} \frac{\partial\ lnV_g^{ij}}{\partial\ lnE^{Cj}}$$

Substituting for $\frac{\partial\ lnV_g^{ij}}{\partial\ lnE^{Cj}}$ from Equation (8)

$$\frac{\partial\ lnV_p^{ij}}{\partial\ lnE^{Cj}} = \frac{1}{\sum_{g=1}^{G} V_g^{ij}} \sum_{g=1}^{G} V_g^{ij}[-(\sigma_g - \omega_g) s_g^{cj} \mu_g^{cj}] = -\sum_{g=1}^{G} \frac{V_g^{ij}}{\sum_{g=1}^{G} V_g^{ij}} [(\sigma_g - \omega_g) s_g^{cj} \mu_g^{cj}]$$

This is Equation (10) in the paper.

Table A1. Summary Statistics
